Radiation Source, Lithographic Apparatus, and Device Manufacturing Method

The present invention relates to a radiation source comprising an anode and a cathode that are configured and arranged to create a discharge in a substance in a space between said anode and cathode and to form a plasma so as to generate electromagnetic radiation. Further, the invention relates to a lithographic projection apparatus having such a radiation source comprising:

- a radiation system for supplying a projection beam of radiation;
- a support structure for supporting patterning means, the patterning means serving to pattern the projection beam according to a desired pattern;
- a substrate table for holding a substrate; and
- a projection system for projecting the patterned beam onto a target portion of the substrate.

The term “patterning means” as here employed should be broadly interpreted as referring to means that can be used to endow an incoming radiation beam with a patterned cross-section, corresponding to a pattern that is to be created in a target portion of the substrate; the term “light valve” can also be used in this context. Generally, the said pattern will correspond to a particular functional layer in a device being created in the target portion, such as an integrated circuit or other device (see below). Examples of such patterning means include:

a mask. The concept of a mask is well known in lithography, and it includes mask types such as binary, alternating phase-shift, and attenuated phase-shift, as well as various hybrid mask types. Placement of such a mask in the radiation beam causes selective transmission (in the case of a transmissive mask) or reflection (in the case of a reflective mask) of the radiation impinging on the mask, according to the pattern on the mask. In the case of a mask, the support structure will generally be a mask table, which ensures that the mask can be held at a desired position in the incoming radiation beam, and that it can be moved relative to the beam if so desired;

a programmable mirror array. An example of such a device is a matrix-addressable surface having a viscoelastic control layer and a reflective surface. The basic principle behind such an apparatus is that (for example) addressed areas of the reflective surface

reflect incident light as diffracted light, whereas unaddressed areas reflect incident light as undiffracted light. Using an appropriate filter, the said undiffracted light can be filtered out of the reflected beam, leaving only the diffracted light behind; in this manner, the beam becomes patterned according to the addressing pattern of the matrix-addressable surface.

5 The required matrix addressing can be performed using suitable electronic means. More information on such mirror arrays can be gleaned, for example, from United States Patents US 5,296,891 and US 5,523,193, which are incorporated herein by reference. In the case of a programmable mirror array, the said support structure may be embodied as a frame or table, for example, which may be fixed or movable as required; and

10 a programmable LCD array. An example of such a construction is given in United States Patent US 5,229,872, which is incorporated herein by reference. As above, the support structure in this case may be embodied as a frame or table, for example, which may be fixed or movable as required.

For purposes of simplicity, the rest of this text may, at certain locations,

15 specifically direct itself to examples involving a mask and mask table; however, the general principles discussed in such instances should be seen in the broader context of the patterning means as hereabove set forth.

Lithographic projection apparatus can be used, for example, in the manufacture of integrated circuits (ICs). In such a case, the patterning means may generate

20 a circuit pattern corresponding to an individual layer of the IC, and this pattern can be imaged onto a target portion (e.g. comprising one or more dies) on a substrate (wafer) that has been coated with a layer of radiation-sensitive material (resist). In general, a single wafer will contain a whole network of adjacent target portions that are successively irradiated via the projection system, one at a time. In current apparatus, employing

25 patterning by a mask on a mask table, a distinction can be made between two different types of machine. In one type of lithographic projection apparatus, each target portion is irradiated by exposing the entire mask pattern onto the target portion in one go; such an apparatus is commonly referred to as a wafer stepper. In an alternative apparatus — commonly referred to as a step-and-scan apparatus — each target portion is irradiated by

30 progressively scanning the mask pattern under the projection beam in a given reference direction (the "scanning" direction) while synchronously scanning the substrate table

parallel or anti-parallel to this direction; since, in general, the projection system will have a magnification factor M (generally < 1), the speed V at which the substrate table is scanned will be a factor M times that at which the mask table is scanned. More information with regard to lithographic devices as here described can be gleaned, for example, from
5 US 6,046,792, incorporated herein by reference.

In a manufacturing process using a lithographic projection apparatus, a pattern (e.g. in a mask) is imaged onto a substrate that is at least partially covered by a layer of radiation-sensitive material (resist). Prior to this imaging step, the substrate may undergo various procedures, such as priming, resist coating and a soft bake. After
10 exposure, the substrate may be subjected to other procedures, such as a post-exposure bake (PEB), development, a hard bake and measurement/inspection of the imaged features. This array of procedures is used as a basis to pattern an individual layer of a device, e.g. an IC. Such a patterned layer may then undergo various processes such as etching, ion-implantation (doping), metallization, oxidation, chemo-mechanical polishing, etc., all
15 intended to finish off an individual layer. If several layers are required, then the whole procedure, or a variant thereof, will have to be repeated for each new layer. Eventually, an array of devices will be present on the substrate (wafer). These devices are then separated from one another by a technique such as dicing or sawing, whence the individual devices can be mounted on a carrier, connected to pins, etc. Further information regarding such
20 processes can be obtained, for example, from the book "Microchip Fabrication: A Practical Guide to Semiconductor Processing", Third Edition, by Peter van Zant, McGraw Hill Publishing Co., 1997, ISBN 0-07-067250-4, incorporated herein by reference.

For the sake of simplicity, the projection system may hereinafter be referred to as the "lens"; however, this term should be broadly interpreted as encompassing various
25 types of projection system, including refractive optics, reflective optics, and catadioptric systems, for example. The radiation system may also include components operating according to any of these design types for directing, shaping or controlling the projection beam of radiation, and such components may also be referred to below, collectively or singularly, as a "lens". Further, the lithographic apparatus may be of a type having two or
30 more substrate tables (and/or two or more mask tables). In such "multiple stage" devices the additional tables may be used in parallel, or preparatory steps may be carried out on one

or more tables while one or more other tables are being used for exposures. Twin stage lithographic apparatus are described, for example, in US 5,969,441 and WO 98/40791, incorporated herein by reference.

5 In a lithographic apparatus the size of features that can be imaged onto a substrate is limited by the wavelength of the projection radiation. To produce integrated circuits with a higher density of devices, and hence higher operating speeds, it is desirable to be able to image smaller features. Whilst most current lithographic projection apparatus employ ultraviolet light generated by mercury lamps or excimer lasers, it has been proposed to use shorter wavelength radiation of around 13 nm. Such radiation is termed
10 extreme ultraviolet, also referred to as XUV or EUV, radiation. The abbreviation 'XUV' generally refers to the wavelength range from several tenths of nm to several tens of nanometers, combining the soft x-ray and Vacuum UV range, whereas the term 'EUV' is normally used in conjunction with lithography (EUVL) and refers to a radiation band from approximately 5 to 20 nm, *i.e.* part of the XUV range.

15 A radiation source for XUV radiation may be a discharge plasma radiation source, in which a plasma is generated by a discharge in a substance (for instance, a gas or vapor) between an anode and a cathode and in which a high temperature discharge plasma may be created by Ohmic heating by a (pulsed) current flowing through the plasma. Further, compression of a plasma due to a magnetic field generated by a current flowing
20 through the plasma may be used to create a high temperature, high density plasma on a discharge axis (pinch effect). Stored electrical energy is directly transferred to the plasma temperature and hence to short-wavelength radiation. A pinch may allow for a plasma having a considerably higher temperature and density on the discharge axis, offering an extremely large conversion efficiency of stored electrical energy into thermal plasma
25 energy and thus into XUV radiation. The geometry of devices, such as plasma focus, Z-pinch, hollow-cathode and capillary discharge sources, may vary, but in each of these types a magnetic field generated by the electrical current of the discharge drives the compression.

Figures 5A to 5E are included to provide background information about the construction and operation of such a discharge plasma radiation source. Figures 5A to 5E
30 show schematically a discharge plasma radiation source according to Prior Art comprising a single discharge element 540 of the Z-pinch hollow-cathode type. The discharge element

540 has cylindrical symmetry and comprises an anode 520 and a cathode 510 connected by an electrically insulating cylindrical wall 525. An aperture 530 is provided in the anode 520 on a central axis B for passing electromagnetic radiation from the discharge element 540. The hollow cathode 510 is provided with an annular aperture 511 around the central axis B, and is further provided with a large cavity 512 behind the aperture 511. The cavity 512 also has an annular configuration around central axis B, and the walls of the cavity are a part of the cathode 510. A discharge power supply (not shown) is connected to the anode 520 and cathode 510 to provide for a pulsed voltage V across the anode-cathode gap inside the discharge element 540. Further, a suitable gas or vapor, is provided by a discharge material supply (not shown) at a certain pressure p between the anode and cathode. Examples of suitable substances are xenon, lithium, tin and indium.

A discharge may take place at low initial pressure ($p < 0.5$ Torr) and high voltage ($V < 10$ kV) conditions, for which the electron mean free path is large compared to the dimension of the anode-cathode gap, so that Townsend ionization is ineffective. Those conditions are characterized by a large electrical field strength over gas or vapor density ratio, E/N . This stage shows rather equally spaced equipotential lines EP having a fixed potential difference, as is depicted in figure 5A.

The ionization growth is initially dominated by events inside the hollow cathode 510 that operates at considerable lower E/N , resulting in a smaller mean free path for the electrons. Electrons e from the hollow cathode 510, and derived from the gas or vapor within the cavity 512, are injected into the anode-cathode gap, a virtual anode being created with ongoing ionization, which virtual anode propagates from the anode 520 towards the hollow cathode 510, bringing the full anode potential close to the cathode, as is shown in figure 5B by unevenly distributed equipotential lines EP. The electric field inside the hollow cavity 512 of the cathode 510 is now significantly enhanced.

In the next phase, the ionization continues, leading to a rapid development of a high density plasma region inside the hollow cathode 510, immediately behind the cathode aperture 511. Finally, injection of an intense beam of electrons e from this region into the anode-cathode gap, also shown in figure 5B, forms the final breakdown channel. The configuration provides for a uniform pre-ionization and breakdown in the discharge volume.

Figure 5C shows that a discharge has been initiated and a low temperature plasma 535 of the gas or vapor has been created in the anode-cathode gap. An electrical current will be flowing within the plasma from cathode 510 to anode 520, which current will induce an azimuthal magnetic field, having magnetic field strength H , within the discharge element 540. The azimuthal magnetic field causes the plasma 535 to detach
5 from the cylindrical wall 525 and to compress, as is schematically depicted in figure 5C.

Dynamic compression of the plasma will take place, as further depicted in figure 5D, because the pressure of the azimuthal magnetic field is much larger than the thermal plasma pressure: $H^2/8\pi \gg nkT$, in which n represents plasma particle
10 density, k the Boltzmann constant and T the absolute temperature of the plasma. Electrical energy stored in a capacitor bank (part of the discharge power supply, which is not shown) connected to the anode 520 and cathode 510 will most efficiently be converted into energy of the kinetic implosion during the full time of the plasma compression. A homogeneously filled constriction (plasma pinch) 550 with a high spatial stability is created.

15 At the final stage of plasma compression, *i.e.* plasma stagnation on the central, or discharge, axis B, the kinetic energy of the plasma is fully converted into thermal energy of the plasma and finally into electromagnetic radiation 560 having a very large contribution in the XUV and EUV ranges (as depicted in figure 5E).

It is generally acknowledged that a number of improvements are
20 required before EUV production by gas discharge plasma can be considered suitable (production-worthy) for large scale production of devices, for instance integrated circuits. These include:

higher conversion efficiency. Current sources typically display a conversion efficiency (ratio of power-out at required wavelength to power-in) of approximately 0.5%,
25 resulting in the majority of the input power being converted into heat;

efficient heat removal (cooling). Two components may be distinguished – peak heat load from plasma jets during discharge and average heat load due to repeated discharge. The area over which the heat can be spread is typically limited, and heat removal becomes critical as power levels and repetition rates are increased to achieve a production-worthy
30 source. Overheating of one or more electrode surfaces may occur, affecting pinch size and position if the geometry of the electrodes changes (deformation); and

stable pulse timing and energy. For use with a projection lithography device, the source should produce a stable output during projection. This can be negatively influenced by, for instance, variations in EUV pulse timing (jitter), variations in pinch position and size, and variations in EUV pulse energy.

5 It is an object of the invention to provide a radiation source that provides production-worthy power levels and repetition rates without risk of overheating.

It is another object of the invention to provide a radiation source having a well-defined timing and well-defined energy of generated pulses (shots) of XUV radiation.

10 It is yet another object of the invention to provide an improved radiation source that provides an enhanced conversion efficiency of electrical energy into radiation.

 In one aspect there is provided a radiation source comprising an anode and a cathode that are configured and arranged to create a discharge within a discharge element in a substance in a space between said anode and said cathode to form a plasma so as to generate electromagnetic radiation, wherein said radiation source comprises a plurality of
15 discharge elements. The substance, for instance, a gas or vapor, may comprise xenon, indium, lithium, tin or any other suitable material. To improve heat dissipation, each discharge element may be only used for short intervals, after which one of the other discharge elements is selected.

 In another aspect, there is provided a radiation source comprising an anode
20 and a cathode that are configured and arranged to create a discharge in a substance in a discharge space between said anode and said cathode to form a plasma so as to generate electromagnetic radiation, wherein said radiation source comprises a triggering device for initiating said discharge by irradiating a surface proximate said discharge space with an energetic beam. This precipitates plasma pinch formation by one or more suitable
25 mechanisms such as disturbing the electrical field inside the cavity, changing the conductivity of a material between the electrodes, supplying material by ablation and/or creating photoionization. Irradiating a surface, for instance, on the anode improves the timing of the plasma pinch formation and thus the timing of the XUV pulse.

 In yet another aspect, there is provided a radiation source constructed to
30 have a low inductance, and comprising an anode and a cathode that are configured and arranged to create a discharge in a substance in a discharge space between said anode and

said cathode to form a plasma so as to generate electromagnetic radiation, wherein said method comprises generally an initial discharge followed by operating said radiation source so as to allow successive discharges to occur due to a substantially self-regulated oscillation within said discharge source. The small dimensions and the superimposition of multiple plasma pinches onto a permanent discharge allows the inductive energy to be divided over multiple plasma pinches, improving the conversion efficiency.

According to a further aspect there is provided a lithographic projection apparatus comprising:

- a radiation system for providing a projection beam of radiation;
- 10 a support structure for supporting patterning means, the patterning means serving to pattern the projection beam according to a desired pattern;
- a substrate table for holding a substrate; and
- a projection system for projecting the patterned beam onto a target portion of the substrate,
- 15 wherein said radiation system comprises a radiation source as described above.

According to a further aspect of the invention there is provided a device manufacturing method comprising the steps of:

- providing a substrate that is at least partially covered by a layer of radiation-sensitive material;
- 20 providing a projection beam of radiation using a radiation system as described above;
- using patterning means to endow the projection beam with a pattern in its cross-section;
- projecting the patterned beam of radiation onto a target portion of the layer of radiation-sensitive material.

25 Although specific reference may be made in this text to the use of the apparatus according to the invention in the manufacture of ICs, it should be explicitly understood that such an apparatus has many other possible applications. For example, it may be employed in the manufacture of integrated optical systems, guidance and detection patterns for magnetic domain memories, liquid-crystal display panels, thin-film magnetic heads, etc. The skilled artisan will appreciate that, in the context of such alternative applications, any use of the terms "reticle", "wafer" or "die" in this text should be

30

considered as being replaced by the more general terms "mask", "substrate" and "target portion", respectively.

In the present document, the terms "radiation" and "beam" are used to encompass all types of electromagnetic radiation, including ultraviolet (UV) radiation (e.g. with a wavelength of 365, 248, 193, 157 or 126 nm) and extreme ultra-violet (EUV) radiation (e.g. having a wavelength in the range 5-20 nm).

Embodiments of the invention will now be described, by way of example only, with reference to the accompanying schematic drawings, in which corresponding reference symbols indicate corresponding parts, and in which:

figure 1 depicts a lithographic projection apparatus comprising a radiation source according to the invention;

figures 2A and 2B depict a radiation source comprising a plurality of discharge elements according to the invention;

figure 3 depicts another embodiment of a radiation source according to the invention;

figure 4 depicts a radiation source comprising a laser triggering unit;

figures 5A to 5E depict a discharge of the hollow-cathode type at various stages of discharge;

figures 6A to 6E depict a discharge element according to the invention at various stages of another type of discharge;

figure 7 depicts the measured characteristics of the discharge element employing auto-triggering;

figures 8A to 8D depict a discharge element according to the invention at various stages of yet another type of discharge; and

figures 9A to 9E depict different ramifications for discharge triggering according to the invention.

The skilled artisan will appreciate that the elements in the figures are illustrated for simplicity and clarity and have not necessarily been drawn to scale. For instance, the dimensions of some of the elements in the figures may be exaggerated relative to other elements to help improve the understanding of the embodiments of the present invention.

Embodiment

Figure 1 schematically depicts a lithographic projection apparatus according to a particular embodiment of the invention. The apparatus comprises:

5 a radiation system LA, IL, for supplying a projection beam PB of radiation, for instance, EUV having a wavelength in the range 5-20 nm. In this particular case, the radiation system also comprises a radiation source LA;

a first object table (mask table) MT provided with a mask holder for holding a mask MA (*e.g.* a reticle), and connected to first positioning means PM for accurately positioning the mask with respect to item PL;

10 a second object table (substrate table) WT provided with a substrate holder for holding a substrate W (*e.g.* a resist-coated silicon wafer), and connected to second positioning means PW for accurately positioning the substrate with respect to item PL;

a projection system ("lens") PL for imaging an irradiated portion of the mask MA onto a target portion C (*e.g.* comprising one or more dies) of the substrate W.

15 As here depicted, the apparatus is of a reflective type (*i.e.* has a reflective mask). However, in general, it may also be of a transmissive type, for example (with a transmissive mask). Alternatively, the apparatus may employ another kind of patterning means, such as a programmable mirror array of a type as referred to above.

Referring to figure 1, the laser-produced or discharge plasma radiation
20 source LA typically produces a beam of radiation as a train of pulses that are synchronized with the operation of the lithographic projection apparatus. This beam is fed into an illumination system (illuminator) IL, either directly or after having traversed conditioning means, for instance a spectral filter. The illuminator IL may comprise adjusting means for setting the outer and/or inner radial extent (commonly referred to as σ -outer and σ -inner,
25 respectively) of the intensity distribution in the beam. In addition, it will generally comprise various other components, such as an integrator and a condenser. In this way, the beam PB impinging on the mask MA has a desired uniformity and intensity distribution in its cross-section.

It should be noted with regard to Figure 1 that the source LA may be within
30 the housing of the lithographic projection apparatus, but that it may also be remote from the lithographic projection apparatus, the radiation beam which it produces being led into

the apparatus with the aid of suitable optical components, for instance, directing mirrors. The current invention and claims encompass both of these scenarios.

The beam PB subsequently intercepts the mask MA, which is held on a mask table MT. Having been selectively reflected by the mask MA, the beam PB passes through the lens PL, which focuses the beam PB onto a target portion C of the substrate W. With the aid of the second positioning means PW (and interferometric measuring means IF), the substrate table WT can be moved accurately, *e.g.* so as to position different target portions C in the path of the beam PB. Similarly, the first positioning means PM can be used to accurately position the mask MA with respect to the path of the beam PB, *e.g.* after mechanical retrieval of the mask MA from a mask library, or during a scan. In general, movement of the object tables MT, WT will be realized with the aid of a long-stroke module (coarse positioning) and a short-stroke module (fine positioning), which are not explicitly depicted in Figure 1. However, in the case of a wafer stepper (as opposed to a step-and-scan apparatus) the mask table MT may just be connected to a short stroke actuator, or may be fixed.

The depicted apparatus can be used in two different modes:

1. In step mode, the mask table MT is kept essentially stationary, and an entire mask image is projected in one go (*i.e.* a single “flash”) onto a target portion C. The substrate table WT is then shifted in the x and/or y directions so that a different target portion C can be irradiated by the beam PB;
2. In scan mode, essentially the same scenario applies, except that a given target portion C is not exposed in a single “flash”. Instead, the mask table MT is movable in a given direction (the so-called “scan direction”, *e.g.* the y direction) with a speed v , so that the projection beam PB is caused to scan over a mask image; concurrently, the substrate table WT is simultaneously moved in the same or opposite direction at a speed $V = Mv$, in which M is the magnification of the lens PL (typically, $M = 1/4$ or $1/5$). In this manner, a relatively large target portion C can be exposed, without having to compromise on resolution.

Figure 2A shows a radiation source LA according to the invention. The radiation source LA comprises a plurality of plasma discharge elements 240, an anode plate 220, and a cathode plate 210. The anode plate 220 and the cathode plate 210 are electrically

isolated from each other. The discharge elements 240 are disposed in a substantially symmetrical arrangement between the anode plate 220 and the cathode plate 210, such that the cathode of each discharge element 240 is electrically connected to the cathode plate 210, and the anode of each discharge element 240 is electrically connected to the anode plate 220. The source LA is mounted to a suitable support frame (not shown) so that it can rotate about axis A in a predetermined direction. Radiation 60 is emitted along an axis B through a corresponding emission aperture 230 in the anode plate 220 when one of the discharge elements 240 is in a predetermined firing position 255. Alternatively, the radiation source LA may be constructed such that radiation is emitted through an emission aperture in the cathode plate 210. Each discharge element 240 may be rotated into the firing position 255 – said firing position 255 is substantially fixed with respect to the lithographic projection apparatus. A discharge power supply (not shown) is connected to the anode plate 220 and cathode plate 210 to provide for a pulsed voltage V across the anode-cathode gap inside each discharge element 240. Further, a suitable substance in the form of a gas or vapor, is provided by a discharge material supply (not shown) at a certain pressure p between anode and cathode. Examples of suitable substances are xenon, lithium, tin and indium.

Figure 2B shows the anode plate 220 in plan view as viewed by the lithographic projection apparatus. Although circular emission apertures 230 are depicted, any geometry can be used, for instance polygon. Similarly, although the anode plate 220 and the cathode plate 210 are depicted as uniform circular discs, any shape or construction may be employed that permits the discharge elements 240 to be repeatedly disposed in the firing position 255. For instance, the shape may be modified to improve cooling, to reduce mass, and/or improve ease of construction. Alternatively, a material may be used without emission apertures 230 if the material is transparent to the emitted radiation 60.

Operation of the radiation source LA is similar to the operation of a Gatling gun. The discharge element 240 at the firing position 255 is operated to produce a plasma pinch, which in turn produces a pulse of radiation 60. After emission of the radiation pulse, the source LA is rotated such that a different discharge element 240 is positioned in the firing position 255. The discharge element 240 at the firing position 255 is operated, and the cycle repeats. Each discharge element 240 is only used once per revolution, giving it

time to recover. Typically, recovery will comprise cooling and restoring of the discharge conditions.

Alternatively, each discharge element 240 may be operated in the firing position 255 for a plurality of plasma pinches before rotation. The number of plasma pinches is related to factors including the heat load, and the time needed to restore the discharge conditions in a discharge element 240.

Although a radiation source LA with eight discharge elements 240 is depicted, the skilled artisan will appreciate that any number of discharge elements 240 can be used. For instance, if each discharge element 240 is fired once and a pulse frequency of 5kHz is required, approximately one thousand discharge elements may be used with a rotational speed of approximately 5 revolutions per second.

Additionally, it may be advantageous to identify the discharge element 240 currently in the firing position 255 for control and/or diagnostic purposes. The addition of a measurement device would enable the discharge elements 240 to be rotated into the firing position 255 in any order, and/or to avoid one or more discharge elements 240 that may be performing inadequately.

The embodiments described rotate in a plane perpendicular to the axis of emission B. Alternatively, as shown in-figure 3, the construction of the source LA may be modified so that the discharge elements 240 rotate about axis A in substantially the same plane as the axis of emission B. The discharge elements 240 are disposed in a substantially symmetrical arrangement between a modified anode plate 320 and a modified cathode plate 310, such that the cathode of each discharge element 240 is electrically connected to the modified cathode plate 310, and the anode of each discharge element 240 is connected electrically to the modified anode plate 320.

The embodiments shown describe the use of discharge elements 240 that are fixed in place, and that are used a multitude of times in their lifetime in the firing position 255. It may be advantageous to modify the radiation source LA such that it employs a continuous supply and removal of single use discharge elements 240, wherein each discharge element 240 is used for one or more times in the firing position 255 before being replaced.

In another alternative, substantially different discharge elements 240 may be

used in one radiation source LA, each discharge element 240 providing a substantially different radiation beam 60 in terms of, for instance, wavelength, cross-section shape, solid angle of emission, size, and/or intensity. Providing these kinds of variations at the source may reduce the complexity of the illuminator and projection lens in the lithographic projection apparatus, especially when dealing with reflective optics.

Additionally, two alternatives may be employed to reduce recovery time: additional cooling of the discharge elements 240, for instance, by forcing air at a predetermined temperature over the surfaces, and/or constructing the radiation source LA with cooling channels carrying a suitable fluid, for instance liquid metals or water; and increasing the electrical current and/or the supply rate of discharge material by separating the discharge elements 240 into a plurality of groups, each group of one or more discharge elements 240 having its own discharge power supply and/or a separate discharge material supply.

The embodiments of the radiation source LA may be modified to employ discharge elements 240 of any suitable type, such as Z-pinch, capillary discharge, plasma focus, hollow-cathode or laser produced plasma devices.

A further aspect is depicted in figure 4. A laser triggering unit 15 is disposed such that it can fire a beam of laser light 380 at a predetermined target in a radiation source LA, without impeding the path of emitted radiation 60 along axis B to the lithographic projection apparatus.

Figures 6A to 6E are used to explain the general principle of pinch triggering using a beam of laser light 380. The figures show a cross-section through a discharge element 240, comprising an anode 20 and a cathode 10 that are electrically isolated. The assembly is substantially sealed, and supplied with a gas or vapor at low pressure, for instance xenon or lithium, from a discharge material supply (not shown). The anode 20 and cathode 10 are connected to a discharge power supply (not shown). Discharge field lines 45 are also shown. Pinch formation is triggered using a suitable beam of laser light 380, for instance wavelength: 254-1060 nm, power: 10-100 mJ in 1-20 ns, diameter: 0.3-1 mm.

As depicted in figure 6A, the discharge element 240 is brought into a state where a pinch is about to form, using the discharge power supply (not shown) and the

discharge material supply (not shown). For instance, the anode 20 is connected to ground, the cathode 10 is connected to an a.c. voltage of 11 kV at 100 Hz, and xenon is supplied at a rate of 4 sccm (standard cubic centimeters per minute). At a predetermined moment in the cycling of the discharge power supply (not shown), the beam of laser light 380 is fired at a predetermined point on the surface of the anode (see figure 6B). The beam of laser light 380 causes a region 337 to be heated, and some of the material 35 will be evaporated from the surface (ablation) as shown in figure 6C. The material ejected 35 enters the discharge region, and triggers the pinch effect (see figure 6D) that results in a constriction (pinch) 50 containing hot plasma (see figure 6E). This plasma has a high resistance due to its small cross-section, and effectively transforms the electrical energy of the discharge into thermal energy of the plasma, and finally into emitted radiation 60 along axis B. After the pinch, the device will return to a state of diffused discharge (see figure 6A).

Triggering in this way eliminates uncertainties in the timing and spatial position of the discharge caused by, for instance, electrode erosion, electrode deformation, variations in the supply rate of discharge material and/or variations in the power supply.

Figure 9A depicts a cross-section through a further embodiment, a discharge element 240 of the hollow-cathode type, comprising an anode 20 and a hollow cathode 10 that are electrically isolated. An aperture 911 is provided in the cathode 10, and an emission aperture 230 is provided in the anode 20. The anode may be composed of any suitable material, for instance tungsten. The assembly is substantially sealed, and supplied with a gas or vapor at low pressure, for instance xenon or lithium, from a discharge material supply (not shown). The anode 20 and cathode 10 are connected to a discharge power supply (not shown). The discharge element 240 is brought into a state where a pinch is about to form, using the discharge power supply (not shown) and the discharge material supply (not shown). At a predetermined moment in the cycling of the discharge power supply (not shown), a beam of laser light 380 is fired at a region close to the emission aperture 230 on the anode 20. Pinch formation and subsequent radiation emission occur in a similar way as depicted in figures 6C to 6E.

The expected method of triggering the pinch is to fire the beam of laser light 380 at a predetermined target on the cathode 10 as depicted in figures 9B to 9E: the rear wall of the hollow cathode 10 (as depicted in figure 9B);

the cathode aperture 911 (as depicted in figure 9C);

a point on the cathode 10 close to the cathode aperture 911 between the cathode 10 and the anode 20 (as depicted in figure 9D); and

a protruding structure (trigger pin) 355 on a surface adjacent to the discharge area
5 between the cathode 10 and the anode 20 (as shown in figure 9E). The trigger pin 355 may be comprised of the same material as the cathode, and/or the solid form of the gas or vapor used to form the plasma, and/or a different material chosen for its evaporation properties. For instance, tin, lithium, indium and iridium may be used.

However, the embodiment (as shown in figure 9A) where the beam of laser
10 light 380 irradiates a part of the anode 20 provides the following advantages:

the position of the pinch and thus the emitted radiation is stable relative to the central axis B, resulting in a stable radiation pulse energy and timing; and

the pinch position is close to the central axis B, so the production of debris caused by electrode erosion is low.

15 It may be advantageous to employ a protruding structure(trigger pin) 355 similar to the one shown in figure 9E, but on a surface of the anode 20 adjacent to the emission aperture 230.

A further alternative is to configure the position and energy of the laser beam 380 such that some or all the discharge material may be provided by ablating
20 material from a suitable surface in the source LA. It may also be advantageous to employ another radiation or particle source instead of a laser beam 380, for instance an electron-beam.

Yet another embodiment of a discharge element 240 is schematically depicted in cross-section in figures 8A to 8E. The discharge element 240 comprises an
25 anode 20 and a cathode 10 that are electrically isolated. The assembly is substantially sealed, and supplied with a gas or vapor at low pressure, for instance xenon or lithium, from a discharge material supply (not shown). The anode 20 and cathode 10 are connected to a discharge power supply (not shown), for instance an a.c. voltage supply capable of operating at 100 Hz (not shown). The discharge field lines 45 are also shown.

30 The discharge element 240 is constructed such that it has a low inductance, for instance less than approximately 20nH. This may be done as follows:

a minimal gap between the cathode 10 and the anode 20, for instance several millimetres;

minimal dimensions of the discharge element 240, for instance a diameter of less than approximately 10mm at the anode;

5 short connections between the discharge power supply (not shown) and the discharge element 240; and

thick electrical connections, for instance using metal plates instead of wires.

At a predetermined moment in the cycling of the discharge power supply, an electrical trigger is created by allowing the current from the discharge power supply to rise quickly (for instance in less than 100 nanoseconds), and by maintaining the current for a
10 predetermined interval of time, for instance 10 microseconds. The quick rise in current is made possible by the low inductance of the system.

As depicted in figure 8A, the discharge element 240 is brought into a state where there is diffuse discharge from a cathode spot 15 to an anode 20. Cathode spots are
15 hot spots that form on the surface on a cathode. They provide the discharge with electrons due to their higher than ambient temperature, and at a high enough temperature, they may supply the discharge with cathode material by evaporation. The current flowing from the cathode 10 to the anode 20 is limited by the discharge power supply (not shown). As
shown in figure 8B, two physical effects occur as the current flows through the system –
20 supply of cathode material from the cathode spot 15 in the form of low temperature plasma 35 into the discharge gap, and compression of the plasma column due to the pinch effect. As shown in figure 8C, the pinch effect results in a constriction (pinch) 50 containing hot plasma. This plasma has a high resistance due to its small cross-section, and effectively transforms the electrical energy of the discharge into thermal energy of the plasma, and
25 finally into emitted radiation 60 along axis B. The high resistance of the constriction 50 causes a current decrease, and the plasma again expands to the walls of the anode as shown in figure 8D. The expansion of the plasma results in the formation of diffuse discharge as depicted in figure 8A. The resistance of a diffuse discharge is lower, and thus the current rises again. By operating the discharge element 240 such that the cathode spot 15 supplies
30 material continuously, the cycle depicted in figures 8A to 8D repeats continuously. Thus, a self-oscillating (auto-triggering) regime with a plurality of emitted radiation pulses 60 is

produced during the predetermined interval of time that the current is maintained by the power supply, for instance, 10 microseconds.

Figure 7 shows measurements on the discharge element 240 during a period of auto-triggering. The graph shows output radiation intensity 701, the current 702 and the voltage 703 of the power supply using lithium vapor as the working substance. The time
5 between pulses 704 is approximately 45ns (equivalent to 22 MHz).

The reduced size of the plasma region means that only a small part of the energy input into the system is used to heat the plasma in the final stage of the pinch. The rest of the energy is either stored as induction or used for plasma creation. This
10 combination of a low-inductance construction with a continuous supply of discharge material results in the superimposition of multiple plasma pinches onto a permanent discharge. The inductive energy is thus divided over multiple plasma pinches, creating a conversion efficiency of at least 2 %.

Alternatively, some of discharge material may be supplied by ablating
15 material from a suitable surface inside the discharge element 240. This can be done using any suitable energetic beam, for instance a laser or an electron-beam.

In another alternative, the formation of the cathode spot 15 at a predetermined position may be encouraged by firing any suitable energetic beam, for instance a laser or an electron-beam at the predetermined position.

20 This embodiment uses an electrical trigger to precipitate the initial pinch formation, and it uses a cathode spot 15 to provide discharge material 35. It may be advantageous to trigger the initial pinch formation using a laser triggering unit as described in earlier embodiments. In this case, initial pinch formation within the discharge element 240 would occur in a substantially similar way to that shown in figures 6A to 6E, where
25 discharge material 35 is supplied by irradiating a predetermined position on a suitable surface inside the discharge element 240. By repeated irradiation of the suitable surface such that the heated region 337 supplies material continuously, an auto-triggering regime can be maintained. The variations in the position of the irradiated surface described in the earlier embodiments are also applicable to this embodiment.

30 Accordingly, the scope of the invention should be determined not by the embodiment(s) illustrated, but by the appended claims and their equivalents.

CLAIMS

1. A radiation source comprising an anode and a cathode that are configured and arranged to create a discharge within a discharge element in a substance in a discharge space between said anode and said cathode to form a plasma so as to generate electromagnetic radiation, wherein said radiation source comprises a plurality of discharge elements.
2. A radiation source according to claim 1, wherein each discharge element is movable in line with an optical axis of an apparatus in which said radiation source is employed.
3. A radiation source according to claim 1 or 2, wherein said discharge elements are arranged around a rotation axis of said radiation source.
4. A radiation source comprising an anode and a cathode that are configured and arranged to create a discharge in a substance in a discharge space between said anode and said cathode to form a plasma so as to generate electromagnetic radiation, wherein said radiation source comprises a triggering device for initiating said discharge by irradiating a surface proximate said discharge space with an energetic beam.
5. A radiation source according to claim 4, wherein said energetic beam is a beam of electromagnetic radiation.
6. A radiation source according to claim 5, wherein said energetic beam is a laser beam.
7. A radiation source according to any claim 4, wherein said energetic beam is a beam of charged particles.
8. A radiation source according to any one of claims 4 to 7, wherein said energetic beam irradiates an area on the surface of an anode.
9. A radiation source according to any one of claims 4 to 7, wherein said energetic beam irradiates an area on the surface of the anode adjacent to an emission aperture.
10. A radiation source according to any one of claims 4 to 7, wherein said energy beam irradiates an area on the surface of a cathode.
11. A radiation source according to any one of claims 4 to 7, wherein said

energetic beam irradiates a target structure on said cathode adjacent to said discharge area.

12. A radiation source according to any one of claims 4 to 7, wherein said energetic beam irradiates a target structure on said anode adjacent to said discharge area.

13. A method for operating a radiation source, constructed to have a low
5 inductance, and comprising an anode and a cathode that are configured and arranged to create a discharge in a substance in a discharge space between said anode and said cathode to form a plasma so as to generate electromagnetic radiation, wherein said method
comprises generally an initial discharge followed by operating said radiation source so as to allow successive discharges to occur due to a substantially self-regulated oscillation
10 within said discharge source.

14. A radiation source according to claim 13, wherein material for discharge is provided by evaporation at the site of a cathode spot.

15. A radiation source according to claims 13 and 14, wherein said initial discharge is initiated by increasing the current through said cathode spot.

16. A radiation source according to claim 13, wherein said initial discharge is initiated by irradiating a surface proximate said discharge space with an energetic beam.

17. A radiation source according to claim 13, wherein said successive discharges are initiated by irradiating a surface proximate said discharge space with an energetic beam.

20 18. A lithographic projection apparatus comprising:
a radiation system for providing a projection beam of radiation;
a support structure for supporting patterning means, the patterning means serving to pattern the projection beam according to a desired pattern;
a substrate table for holding a substrate;
25 a projection system for projecting the patterned beam onto a target portion of the substrate,

wherein said radiation system comprises a radiation source according to any one of the claims 1 to 17.

19. A device manufacturing method comprising the steps of:
30 providing a substrate that is at least partially covered by a layer of radiation-sensitive material;

providing a projection beam of radiation using a radiation system comprising a radiation source according to any one of the claims 1 to 17;

using patterning means to endow the projection beam with a pattern in its cross-section;

- 5 projecting the patterned beam of radiation onto a target portion of the layer of radiation-sensitive material.

ABSTRACT

**Radiation Source, Lithographic Apparatus,
Device Manufacturing Method, and Device Manufactured Thereby.**

A radiation source comprises an anode and a cathode that are configured and arranged to create a discharge in a gas or vapor in a space between anode and cathode and
5 to form a plasma pinch so as to generate electromagnetic radiation. The gas or vapor may comprise xenon, indium, lithium and/or tin.

To improve heat dissipation, the radiation source comprises a plurality of discharge elements, each of which is only used for short intervals, after which another discharge element is selected.

10 To improve the exact timing of the pinch formation and thus the pulse of EUV radiation, the radiation source comprises a triggering device.

To improve the conversion efficiency, the radiation source is constructed to have a low inductance, and operated in a self-triggering regime.
